ACKNOWLEDGMENT

The tables presented in this volume are the results of one phase of a fire damage appraisal study undertaken by the Forest Fire Research and the Forest Influences Divisions of the California Forest and Range Experiment Station in cooperation with the four southern California national forests. The project was sponsored and partially financed by the California Region of the Forest Service.

The major portion of the basic data used in the analysis leading to the results here presented were obtained from information published by, or made available through the courtesy of the U. S. Geological Survey, Los Angeles County Flood Control District, Los Angeles office of the U. S. Engineers, U. S. Weather Bureau, and many local agencies.

Grateful acknowledgement is made to C. C. Buck and W. L. Fons of the Experiment Station Forest Fire Research Division for thier assistance in the collection and compilation of the basic data and for their critical reviews and suggestions concerning this publication.

Much credit is also due members of the Division of Forest Influence staff, particularly J. S. Morton, who was directly resposible for the vegetation surveys; E. A. Colman, who was responsible for the initial soil-geologic surveys; and J. P. Sinclair for his effective liaison work and his critical review and suggestions concerning this publication.

PROBABLE PEAK DISCHARGES AND EROSION RATES FROM SOUTHERN CALIFORNIA WATERSHEDS AS INFLUENCED BY FIRE

By P. B. Rowe, C. M. Countryman, and H. C. Storey
California Forest and Range Experiment Station[1]/

1/ Maintained by the Forest Service, U.S. Department of Agriculture, in cooperation with the University of California, Berkeley, California.

INTRODUCTION

Damages from floods and erosion have been a serious problem in southern California since early pioneer days. The problem is becoming even more serious as the rapidly increasing population and expanding industrial and agricultural development encroach upon the flood plains and extend up the steep slopes and into canyons of the nearby mountains. Protection of forest vegetation from fire is an extremely important factor in maintaining damages at a minimum. The removal of the vegetative cover of the mountain watersheds by fire greatly increases the flood peaks and erosion rates with a consequent increase in flood and erosion damage. Estimates of the amount of damage, both actual and potential, caused by increased flood and erosion as a result of fires, therefore, are essential in checking the adequacy of present fire protection and in planning protection levels in keeping with the values involved.

This publication presents the results of one phase of a study seeking a uniform method of making such estimates for the national forests of southern California. The immediate objective of this phase of the study was to provide basic hydrologic information by (1) estab-

lishing reasonable estimates of the average frequency and size of flood events and erosion rates with watershed vegetation in normal condition, that is, fully recovered from past burns, and (2) determining the effect of burning the vegetation on those flood peaks and erosion rates.[2] Hydro-

---

2/ The flood and erosion damages attributable to fire that were developed from this hydrologic information are given in the following publications of the California Forest and Range Experiment Station:

Fire Damage From Increased Run-off and Erosion, Angeles, Cleveland, San Bernardino, and Los Padres National Forests (in separate volumes), by Charles C. Buck, Wallace L. Fons, and Clive M. Countryman. 1948.

Average Fire Damage From Increased Run-off and Erosion on the Southern California National Forests, by Charles C. Buck, Wallace L. Fons, and Clive M. Countryman. 1948.

---

logic data of this kind are critically needed for management of mountain watersheds in southern California. For this reason the results of this phase of the study are presented here, in advance of detailed discussion of the analysis, to make the data immediately available for those having need of such information.

The estimates of peak discharge[3] and erosion[4] are given for 256

3/ Peak discharge as used in this paper is the maximum instantaneous rate of transient flow (green stage) from given watersheds for individual storm events, expressed in cubic feet per second per square mile.

4/ Erosion rate, as used in this paper, is the volume of eroded material discharged from given watersheds expressed in cubic yards per square mile per year.

---

watershed units with a combined area of approximately 6800 square miles. These watershed units embrace a major portion of the higher mountain drainages in a 20- to 80-mile wide strip extending along the coast from the Mexican border to watersheds a few miles north of San Luis Obispo.

Long dry summers and short winter rain seasons characterise the climate of the region. The mountain ranges, which lie across the path of the principal storms, are a major influence on the rainfall of the area. They lift and cool storm air masses moving inland from the ocean, an action often resulting in very intense precipitation. Rates of rainfall as high as 1.02 inches in one minute, and 26.20 inches in 24 hours have been recorded. Average annual precipitation varies widely over the area, ranging from 10 inches in the interior valleys to more than 38 inches in the higher mountain drainages.

Most of the drainages are small, generally fan shaped, with short, steep stream channels and precipitous side slopes. Such topographic characteristics are conducive to rapid concentration of run-off and when combined with intense rains are a primary cause of the high peak discharge and erosion rates of the region.

Brush, or chaparral, is the most extensive vegetative cover type of the region, occupying nearly 68% of the area. Open woodlands cover about 21% of the area and coniferous forests nearly 11%. Fires are usually less frequent and less severe in the woodland and coniferous forests than in the brush types. Severe or repeated turning in these types, however, often results in their replacement by brush.

GENERAL ANALYSIS PROCEDURE

The minimum study area used in making the estimates of peak discharge and erosion rates was a "watershed unit" (fig. 1). Each watershed unit was on upstream portion of a single stream or major tributary, or two or more similar small front drainages with separate discharge channels. The lower boundaries of the units were established by the specifications

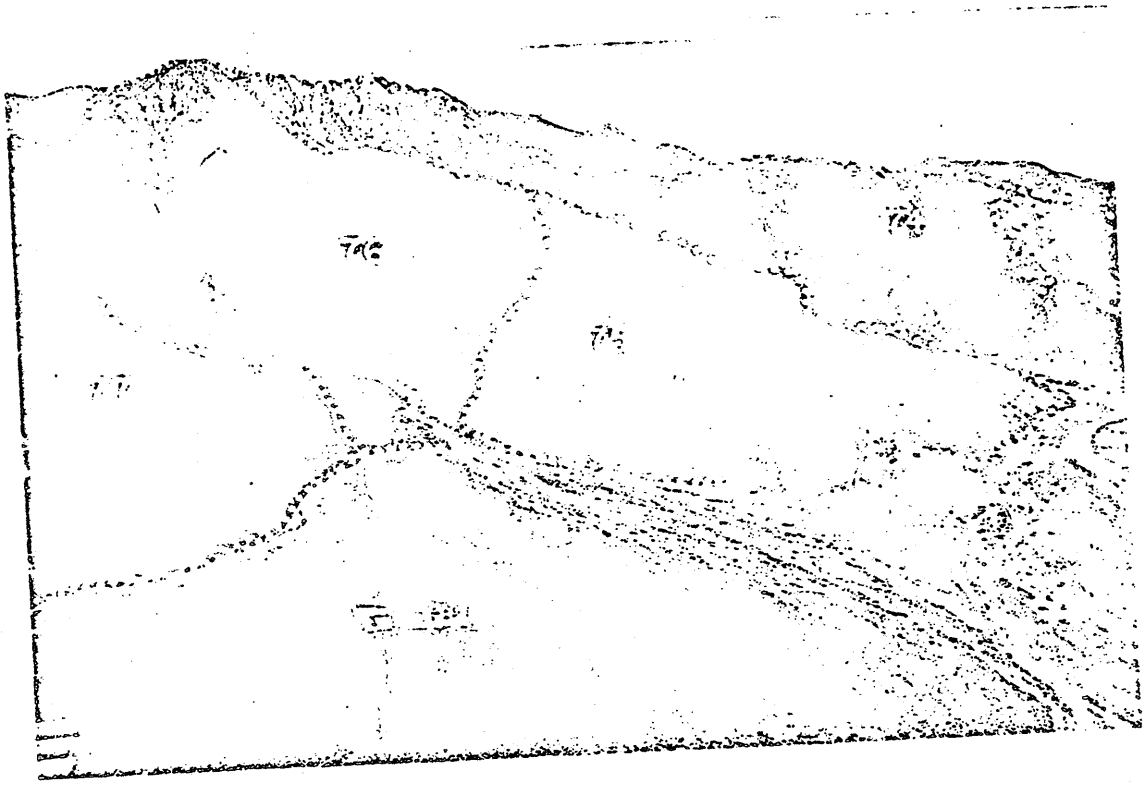
of the economic phase of the study, and generally followed the boundary between inflamable watershed cover and valley agricultural lands.

Figure 1.--Typical watershed unit delimitation. Units 74 and 76 illustrate watershed units having a single major stream. Units 75 and 77 are typical "front" units containing a group of similar, small drainages with separate drainage channels.

The units were grouped into five general "storm zones" (see Plate A), each zone consisting of a serious of adjacent watershed units which receive storms of approximately uniform characteristics and frequencies. The effect of fire on peak discharge was found by (1) establishing the relation between storm precipitation and peak discharge for a key watershed in each storm zone, (2) developing from this relation normal peak discharge frequencies for all watershed units in the zone, and then (3) determining the changes in normal peak discharge in the years following a fire. The effect on erosion was found by developing annual erosion rates for the normal discharge frequencies and determining the effect of fire on these rates.

DETERMINATION OF NORMAL PEAK DISCHARGE FREQUENCIES

A representative precipitation station having a 60 to 80 year record was selected as a key precipitation station for each storm zone. The number of storms of various sizes were then tabulated from the rainfall record of the station. The maximum recorded twenty-four hour precipitation of each storm was used to establish the size of the storm. From this tabulation a frequency curve was developed giving the average number of storm events per year by storm class for the storm zone.



CHO 2110

Figure 1.- Typical watershed unit delimitation. Units 74 and 76 illustrate watershed units having a single major stream. Units 75 and 77 are typical "front" units containing a group of similar, small drainages with separate drainage channels.

The relation between the size of storm events at the key station and those on a typical unburned key watershed was determined from Isohyetal maps and precipitation stations within the key watershed. Relations between the observed peak discharge on the key watershed and the 24-hour maximum watershed precipitation were then established. These relations were used to determine the number and size of discharge events during the period of record and to establish the peak discharge frequency curve. When necessary the observed peak discharge frequencies were adjusted to conform to those of the longer period represented by the key station storm frequencies. The peak discharge frequencies of other watersheds for which discharge measurements were available were computed by establishing the relation between observed discharges of each watershed and those of the key watershed in their storm zone.

Since discharge measurements were available for only a relatively few watersheds, the peak discharges derived form the observed data were used to establish a system of watershed ratings to aid in making estimates of peak discharge for units without discharge records. These ratings were an expression of the total effect upon peak discharge of the watershed factors of size, shape, steepness, stream channel characteristics, infiltration and water storage capacities of various soil-geologic formations, and precipitation and vegetation characteristics. These watershed ratings were expressed as ratios between normal peak discharges of the key watersheds and peak discharges of each of the other watersheds. After being thoroughly tested against observed data the ratings were used to compute the normal peak discharges of these watersheds for which data were inadequate or not available.

Determination of Effect of Fire on Peak Discharge

Determination of the effects of complete burning[5]/ of the watershed vegetative cover on peak discharge were made in two ways: by comparing peak discharge rates of burned watersheds with those of similar but unburned watersheds[6]/ for the same storms, or by comparing peak discharge rates from similar storms on the same watershed before and after burning. From these ways a series of curves showing the average effects of complete burning on normal peak discharge by years after burn were developed for each storm zone.

5/ Complete, part, or partial burning as used in this paper refer to the proportion of a watershed area burned over by a fire and not to the intensity of the burning or to the degree to which the vegetation cover was consumed by the burning.

6/ Unburned watersheds were considered as those watersheds in which the vegetation has sufficiently recovered from past fires (if any), so that the effect of the past fires on peak discharge and erosion could be considered negligible.

The average-effect-of-burning curves were adjusted to conditions of individual watersheds by applying corrections for the variations in type and density of cover, and for differences in proportion of burnable area. Burnable areas include those that have a vegetation cover of such type and density that its removal by fire will cause appreciable increase in peak discharge and erosion rates. Non-burnable areas are of two types: first, those having insufficient vegetation cover to carry a fire, and second, those having an open cover which may burn under extreme fire conditions but which, if burned, would not result in appreciable increase in the peak discharge and erosion rates. The first includes agricultural and cleared lands, rock areas, and barren Alpine and desert slopes. The second are comprised principally of areas of Alpine and other open forest cover without brush underatories, open desert chaparral and pinyon juniper types, and steep and rocky slopes with open chaparral and sage cover of less than 25 percent density. These so-called non-burnable areas are excluded in computing fire effects. Probable peak discharges of the individual watersheds by years after burning were computed from the normal peak discharge and the adjusted effect-of-burning curves.

For the majority of the watersheds the effect on peak discharge of burning part of the watershed was assumed to be directly proportional to the area burned. In some watersheds, however, such factors as size and shape of the watershed, length of stream channels, and differ-

ences of concentration time modified considerably the influence of partial burns. In such watersheds weighted reductions in the increase in peak discharges resulting from fire were made to compensate for the average influence of those factors.

In the San Bernardino storm zone[7]/ snowfall in some portions

---

7/ Tables 37 to 96, inclusive.

---

of the area has a decided effect on peak discharge. In general, the effect of snow is to decrease the storm peak discharge for a given amount of precipitation, thus increasing the proportion of smaller peak discharge. To allow for the effect of snow, watershed units in this zone were classified as to high, moderate, or low snow effect and a discharge-frequency curve was developed for each class. The class to which each unit of the San Bernardino storm zone was assigned is indicated on the peak discharge and erosion tables.

Determination of Annual Erosion Rates

Estimates of normal erosion were made principally from measurements of sedimentation in reservoirs. The sedimentation records, although generally short, were available for periods that usually included a wide variety of discharge occurrences. The volume of material deposited in reservoirs between measurements was prorated in amounts proportional to the carrying power of the individual peak discharges recorded during the period. The relation between the computed erosion rates and individual peak discharges was established for each watershed for which data were available. Curves representing the average relation between peak dis-

charge and erosion rates were then developed from these computations. These average curves were used to determine the normal annual erosion rates for each of the watershed units. Because the objective of the study was to determine the effects of fire only, adjustments in erosion rates were made for watersheds influenced by excessive grazing, road construction, or established gullies.

Determination of the Effect of Fire on Annual Erosion Rates

Determination of the effects of complete burning on the average annual erosion rates of individual watersheds was made by comparing erosion rates of burned watersheds with those of similar unburned watersheds. The weighted average ratios between normal annual erosion rates and the annual erosion rates following burning were then computed. These ratios, corrected for variation in proportion of burnable areas, were used in computing probable erosion rates of the individual watersheds by years from time of burning until return to normal.

Effects of partial burning of a watershed on erosion rates were assumed to be directly proportional to the area burned.

USE OF THE PEAK DISCHARGE AND EROSION TABLES

The storm peak discharges and annual erosion that can be expected from a watershed in any one season depend on, among many other things, the number and frequency of the storms and the amount and intensity of the precipitations. Since there is no way of forecasting what the character and number of storms will be in a given period in the future, the estimates of peak discharge and annual erosion presented are simply averages, or the most probable rates expected over a long period of time. Number end rise

discharge events and amount of annual erosion for individual seasons will thus vary from those indicated in Tables 1-256, which are given at the end of this report.

What the Tables Show

Methods used in the economic analysis of flood and erosion damage dictated the form in which the flood peak discharge and erosion estimates appear. Normal (70th year after burn) peak discharges are given as the weighted means of relatively small discharge classes (see fig. 2). Frequency of storm events is shown as the average total number of events per year within the discharge class. For example, in the Santa Anita unit (table 134, duplicated here for easy reference) the first discharge class has an average of 16.628 storms per year with a weighted average peak discharge of 0.85 CFS/sq. mi. The second discharge class has an average of 1.579 storms per year with an average peak discharge of 7.10 CFS/sq. mi. The sum of the number-of-events-per-year column, 21.095 for Santa Anita, indicates the average total number of storms per year for the storm zone.

Figure 2--Normal peak discharge frequencies for Santa Anita Watershed, Los Angeles storm zone.

Frequencies of peak discharges of a site equaled or exceeded less frequently than once in one hundred years were not determined. Thus the figures shown in the last line of section A of the tables are not the mean of a discharge class as are the proceding data, but rather indicate the peak discharge that will be equaled or exceeded on the average once in one hundred years.

B. Annual Erosion Rates Following Burning

Years after burning: 1	2	3	4	5	6	7	8	10 (Normal)
(Cubic yards per square mile)								
133,000	46,360	30,020	20,900	14,820	10,260	6,840	4,070	3,800

The effect of fire is indicated by showing how the normal storm peak discharge is increased for various years after burning. Again using the Santa Anita unit (table 134) as an example, the normal discharge of the first discharge class for the unburned watershed is 0.85 CFS per square mile. The first year after a complete burn peak discharges of this class would be increased to an average of 28.9 CFS/sq. mi., the second year to 5.09 CFS/sq. mi, the third year to 2.80 CFS/sq. mi., etc.

Tables A and B give the necessary information for duplicating the peak discharge-frequency curves used in obtaining the values in the peak discharge tables. Peak discharges given for any year after burn may be plotted against the logarithmic mean number of events, shown in tables A and B, for the storm zone in which the watershed unit is located to develop the discharge-frequency curve for that year after burn (see fig. 2).

Erosion rates shown by the available data, on the average returned to approximately normal by 10 years after the fire. Thus in section B of the peak discharge and erosion tables, which shows average annual erosion rates by years after burning, the normal rate is that for the tenth year after burning.

Application of Tables to Individual Watersheds

Besides showing the average number and size of peak discharge events and the effect of fire on peak discharge, the tables have several other uses with direct application to the watersheds for which they were compiled.

Estimates of the effect of burning on individual peak discharges following a fire are often desired. If the storms following the complete burning of a watershed follow average trends, this may be done simply by comparing the peak discharges that occur with those of the same frequency

under normal conditions of cover. For example, suppose the vegetative cover of the Santa Anita unit (table 134) were completely burned and a peak discharge of 335 CFS/sq. mi. were recorded the second season following the burn. If the storms preceding this discharge followed average trends, the peak discharge of the unit in an unburned condition would have been 180 CFS. Since there is no assurance that storms for any short period will follow average trends the frequency of discharge should be checked by comparing it with similar adjacent unburned watersheds. If the peak discharges all fall in about the same frequency class, 0.0192 in this case, than the 180 CFS/sq. mi. discharge for Santa Anita can be assumed to be reasonably accurate. However, if the peak discharges of the comparative units fall in a different frequency class, then the normal peak discharge of that same class for Santa Anita would be a better estimate of the normal peak discharge for this storm than would the discharge of the 0.0192 frequency class.

The tables can also be used to determine the peak discharge that will be equaled or exceeded at any given frequency. For example, one may wish to know for the Santa Anita watershed (table 134) what size discharge will be equaled or exceeded once in 10 years. The most precise method of obtaining this information would be to plot the peak discharges for normal watershed conditions, or desired year after burn, against the logarithmic means of the basic frequency classes given for the Los Angeles storm zone in table A. This will give the peak discharge-frequency curve (see fig. 2). The peak discharge equaled or exceeded once in ten years can then be read directly from this curve. An approximate value can be more quickly obtained from the peak discharge tables. For example, the total of the last eleven

items (0.0100, 0.0021, 0.0027, 0.0034, 0.0044, 0.0056, 0.0074, 0.0099, 0.0140, 0.0192, 0.0271) of the frequency column is 0.1058 storms per year, or slightly more than an average of one storm in ten years. This indicates that there would be a storm with a peak discharge that would exceed that of the .0414 frequency class (12th item from bottom of column) on an average of about once in ten years. The upper limit of this class is approximately midway between its mean peak discharge and that of the .0271 class. Thus the peak discharge that would be equaled or exceeded on an average of about once in ten years for normal watershed cover would be between 135 and 158 CFS/sq. mi. or approximately 147 CFS/sq. mi. If this storm were to occur the first year after burning the peak discharge equaled or exceeded would fall between 345 and 384 CFS/sq. mi. or would be approximately 365 CFS/sq. mi.

The same procedures used in determining the peak discharges that will be equaled or exceeded once in ten years can be used to determine those that will be equaled or exceeded in any desired period of less than 100 years.

Use of Tables in Computing Effects of Partial Burns

Only occasionally do fires completely burn off the vegetation of an entire watershed, but effects of partial burning can be estimated by use of the peak discharge tables. In making these estimates it is necessary to know not only the type of the watershed (runoff concentration characteristics) but also its burnable area. The percent of the watershed considered burnable and the watershed type (I. II, or III) are shown on the peak discharge and erosion tables.

Type I watersheds are relatively small, steep, fan-shaped units conducive to rapid concentration of run-off. The effects of partial burns in this type were assumed to be directly proportional to the amount of burnable area burned (fig. 3). Type II watersheds are larger and have longer main stream channels with longer run-off concentration time. Type III watersheds are the largest units, with very long main stream channels, and quite long periods of concentration. The effects of partial burns in these two types are not directly proportional to the area burned, small burns having relatively less effect on increasing peak discharges than the large burns--as shown in Figure 3.

Figure 3--Relation between proporation of burnable area burned and average increase in peak discharge rating for three types of watershed.

The following steps are required to determine the effects of a partial burn on increasing peak discharge for any frequency class and year after burn:

1. Compute the percent of burnable area burned. This may be done by dividing the percentage of total area burned by the percent of the watershed that is burnable (as given at the top of the individual table), and multiplying by 100.
2. From the curves in Figure 3 determine the average increase in the peak discharge rates for the percent of burnable area burned (as obtained in step 1).
3. Subtract the normal (70th year after burn) peak discharge of the frequency class from the tabulated peak discharge for the year after burn for which the peak discharge is desired.

Figure 3.- Relation between proportion of burnable area burned and average increase in peak discharge ratio for three types of watersheds.

PROPORTION OF BURNABLE AREA BURNED (%)

Figure 3

This will give the amount of increase in peak discharge as the result of a complete burn.

4. Multiply the increase in peak discharge for complete burn (obtained in step 3) by the increase in peak discharge ratio (step 2). The result will be the increase in peak discharge from the partial burn.
5. Add the increase in peak discharge resulting from the partial burn (step 4) to the normal peak discharge for the frequency class to get the total peak discharge following the partial burn.

Following the above procedure for all frequency classes and years after burn, a peak discharge table for any partial burn can be computed. Such a table can be used in exactly the same ways as the peak discharge tables for complete burn given in this publication.

Annual erosion rates following partial burning of a watershed cover were assumed to be directly proportional to the burnable area burned. To complete the erosion rate following a partial burn the difference between the normal erosion rate and the erosion rate for the desired year after burn is multiplied by the percent of burnable area burned. This result added to the normal rate given the total annual erosion rate.

PEAK DISCHARGE AND EROSION TABLES

The following tables give the most probable average peak discharge and annual erosion rates for the watershed units studies. The tables are grouped by storm zones, with a map showing the locations of the units within

each zone preceding the group of tables for that zone. Except where noted below, the tables are numbered to correspond to the numbers of watershed units shown on the maps:

Storm zone	Watershed unit and table no.
Santa Ysabel	1 to 28
San Juan	29 to 36
San Bernardino[8]/	37 to 97

8/ Table 66 gives the most probable peak discharges and erosion rates for the combined area of watersheds 63, 64, and 65.

Table 96 gives the most probable peak discharges and erosion rates for the combined area of watershed units 92, 93, 94, and 95.

Los Angeles	98 to 235
Santa Maria[9]/	236 to 256

9/ Table 247 gives the most probable peak discharges and erosion rates for the Santa Maria River above latitude 34" 54' 8" and longitude 120" 18' 1".

Table 248 gives the most probable peak discharges and erosion rates for the Santa Maria River above Pugler's Point.
